INTRODUCTION

Patients in neuroscience intensive care unit (NSICU) frequently require invasive mechanical ventilation for concomitant respiratory failure. Intensivists need to pay special consideration to patients with elevated intracranial pressure (ICP) on invasive mechanical ventilation, particularly to ensure the maintenance of normal brain tissue oxygenation and optimal partial pressure of carbon dioxide (PCO$_2$) levels, and to provide sedation that achieves both comfort and optimal patient-ventilator synchrony. We report a case of a life-threatening complication of refractory ICP elevation and a well-recognized complication of invasive mechanical ventilation—pneumomediastinum. The pathophysiological mechanisms and proposed treatment strategies are discussed.

CASE REPORT

A 26-year-old man with a distant history of chronic myelogenous leukemia and pectus excavatum and a posterior fossa tumor requiring biopsy, decompression, and cerebrospinal fluid diversion developed pneumomediastinum following intubation with tension physiology and progressive elevation of intracranial pressure. Emergent tracheostomy was performed to decompress intrathoracic pressure, augment venous return, and ultimately expedite the patient’s definitive cancer therapy.

Background: Timely recognition and intervention for venous outflow obstruction due to intrathoracic pathology are critical for controlling elevated intracranial pressure.

Case Report: A 26-year-old man with pectus excavatum and a posterior fossa tumor requiring biopsy, decompression, and cerebrospinal fluid diversion developed pneumomediastinum following intubation with tension physiology and progressive elevation of intracranial pressure. Emergent tracheostomy was performed to decompress intrathoracic pressure, augment venous return, and ultimately expedite the patient's definitive cancer therapy.

Conclusion: Recognition of the mediastinal pathology leading to venous obstruction may be required for the management of malignant intracranial hypertension. Tracheostomy may be a means to decompress mediastinal pressure and augment venous outflow in rare cases of pneumomediastinum with tension physiology.

Keywords: Mediastinal emphysema; Intracranial pressure; Case report
leukemia presented to the emergency department with headache, nausea, and vomiting. Computed tomography of the head revealed bilateral cerebellar lesions with surrounding vasogenic edema, resulting in a mass effect on the fourth ventricle and early tonsillar herniation. Subsequent biopsy was consistent with myeloid sarcoma, and the patient was started on steroids and whole-brain radiation. An external ventricular drain was placed due to progressive obstructive hydrocephalus on hospital day 7, but with progressive elevation of ICP, drowsiness, and poor tolerance of airway secretions, he was intubated and underwent suboccipital craniectomy on hospital day 12, with subsequent improvement of his ICP and associated symptoms. Postoperatively, the patient remained drowsy and struggled with impaired bulbar function and an inability to clear secretions, requiring continuous neurologic monitoring and prohibiting planned therapy with intrathecal chemotherapy and radiation. Although hemodynamically uncompromised, he ultimately needed reintubation due to respiratory fatigue on hospital day 14. Following an uncomplicated intubation, he was noted to have neck swelling and an increasing ICP trend. A computed tomography of the head and neck was ordered to rule out hematoma development in the setting of a recent suboccipital craniotomy (Fig. 1).

However, a post-intubation chest radiograph and subsequent examination revealed the presence of a new pneumomediastinum and subcutaneous emphysema (SQE) (Figs. 2 and 3). The patient continued to deteriorate clinically with rising ICP despite deep sedation. He had declining oxygen saturation despite a new 80% fraction of inspired oxygen (FiO₂) requirement and the application of 6 cmH₂O of positive end-expiratory pressure. He also had been developing hypotension with intermittent electrical alternans that required the initiation of vasopressors. Tension physiology impairing the intracranial venous drainage was suspected. An emergent tracheostomy was performed to relieve the patient’s tension pneumomediastinum while anticipating prolonged intubation, which might otherwise have limited his access to definitive therapy. Standard tracheostomy was performed midway between the sternal notch and thyroid cartilage at the level of the second tracheal ring, and allowed to heal by secondary intention to allow air to dissect across planes and relieve tension. A tracheostomy was successfully performed, resulting in decreased neck swelling, SQE, and pneumomediastinum. His ICP was noted to immediately decrease to 12–15 mmHg at the time of tracheostomy completion and remained stable for the following days; vasopressors were discontinued, and his oxygen requirements resolved. A limited proximal airway survey at the level of the segmental bronchi revealed no notable tracheal injury. The patient tolerated the transfer out of the NSICU for radiation therapy two days later.
mately, he required a ventriculoperitoneal shunt and was decan-
nulated prior to being discharged home after a 103-day length of
stay.

DISCUSSION

Successful management of intracranial hypertension is crucial to
mitigate morbidity and mortality in neurocritical care. The tiered
approach recommended for treatment starts with tier 0, which in-
cludes the management of pain, fever, anxiety, and proper posi-
tioning of the patient. Neutral positioning of the neck and eleva-
tion of the head of the bed to 30°; the proposed mechanism is the
maximization of cerebral venous outflow and subsequent lower-
ing of ICP [1]. Our case demonstrates how proper assessment of
the cardiovascular and respiratory systems and early recognition
of this rare complication can lead to improvements in our ap-
proach to lower ICP.

Intracranial pathology leading to acute respiratory failure may,
in turn, intensify detrimental effects on the acutely injured brain.
Respiratory failure, whether secondary acute hypoxic, hypercap-
nic, or ineffective ventilation due to inability to protect the airway
from secretions or upper airway obstruction, is common in the
NSICU [2]. The cilia of the nasopharynx function to propel se-
cretions in a caudal direction, whereas those of the lower airways
propel secretions in a cephalad direction. These secretions then
accumulate in the pharynx to be swallowed or expectorated
through complex airway protective mechanisms, which may be
significantly impaired in neurological injury [3,4]. In the present
case, posterior fossa pathology and direct brainstem compression
leading to bulbar pathology presented a risk of acute aspiration
and respiratory insufficiency. Increased work of breathing in pa-
tients with limited arousal and variable strength requires vigilance
that may prohibit disposition from the intensive care unit or, as in
this case, lead to intubation for airway protection.

Pneumomediastinum is a rare complication of intubation, al-
though it was likely a higher risk in our patient due to the baseline
anatomic abnormality of the pectus excavatum. Air accumulation,
worsened by the application of positive pressure ventilation, led to
rapid accumulation of mediastinal and subcutaneous air. Pneu-
omediastinum, with or without SQE, is a well-recognized comp-
lication of invasive mechanical ventilation. Alveoli may rupture
due to different mechanisms, including alveolar hyperinflation
and/or dynamic airway obstruction with increased intra-alveolar
pressure. Air then escapes the alveolar space into the interstiti-
urn, dissecting its way from the peri-alveolar space following the bron-
chovascular structures to the hilum, and then accumulates in the
mediastinum and up to the soft tissue of the neck, resulting in
pneumomediastinum and concomitant SQE. This ascending
pathway was described by Macklin [5] in 1939.

Pneumomediastinum is usually benign and well-tolerated by
most patients. However, tension physiology has been described
experimentally in the works of Macklin [5] through compression
of the pulmonary veins, leading to increased afterload of the right
ventricle. While pneumomediastinum does not typically cause
rapid pressurization of the intrathoracic space, chest wall and pa-
renchymal compliance may be restricted by the underlying ana-
tomic or pathologic conditions. Patients may develop pneumo-
pericardium and tension physiology that resembles tamponade
[6,7]. If sufficient to cause hemodynamic compromise and shock,
particularly obstructive physiology with evidence of electrical or
pulsus alternans, narrowing of pulse pressures, and worsening hy-
poxia and/or hypotension, it follows that venous return from the
intracerebral vasculature to the right heart will be limited [8]. In
our case, the patient had progressive tension pneumomediasti-
num, likely in the setting of chronic restrictive lung disease; this
clinically resulted in the direct compression of intrathoracic struc-
tures as well as vasculature in the neck, leading to a rapid rise in
in
dracranial pressure and clinical deterioration.

Treatment of pneumomediastinum is usually achieved conser-

tively if not associated with hemodynamic compromise or oth-
er end-organ perfusion compromise (i.e., tension pneumomedia-
tinum), and it may take one to two weeks for air to be fully ab-
sorbed in the absence of additional inspiratory pressures. On the
other hand, tension pneumomediastinum can be fatal if not rec-
ognized and treated promptly. Similar to treating tension pneu-

mothorax, rapid decompression of air to equilibrate the pressure gradient is desired. Surgical decompression (i.e., mediastinotomy) proposed by Macklin can be achieved through chest tube insertion in the subxiphoid region or through a simple suprasternal incision [5,8]. A simple incision might be more appealing in cases with no continuous air leak or in emergent conditions in which there is clear communication between the mediastinal air and suprasternal subcutaneous tissue.

Our patient developed refractory ICP elevation, hemodynamic compromise, and evidence of rapidly progressive obstructive shock, all of which resolved immediately after performing tracheostomy. Although higher than suprasternal mediastinotomy, pressurized air dissection through tissue planes along the path of least resistance to a tracheotomy site was sufficient to depressurize the neck and thorax, alleviating direct compression of the jugular veins and mediastinal structures, allowing right ventricular filling, and consequently, promoting cerebral venous drainage. We postulate that there is a critical pressure point beyond which further accumulation of air in the mediastinum leads to impaired venous drainage in the brain. In patients with refractory ICP elevation, we propose to routinely assess for the presence of SQE and pneumomediastinum. To our knowledge this is the first case of an adult with refractory ICP elevation due to pneumomediastinum. Furthermore, decompression of the pneumomediastinum is not often necessary, and tracheostomy may be considered in the rare event when intervention is required.
